We applied the simulation method of Mangel et al. (2010) to estimate probable values of stock-recruitment steepness for a Beverton-Holt stock-recruitment curve for North Pacific albacore (*Thunnus alalunga*). Information on albacore life history parameters from the proposed stock assessment model for North Pacific albacore was gathered. This included information on growth, maturity at age, average weight at length, natural mortality rate and reproductive ecology of albacore tuna (Table 1).

There were three growth scenarios considered for North Pacific albacore: these were the Suda growth curve, the Wells growth curve, and the model-based estimate of a growth curve for albacore (Table 1). The parameters of these alternative growth hypotheses were used to construct alternative estimates of prior distributions for albacore steepness.

There was limited information available on the reproductive ecology of albacore. We rescaled the estimated batch fecundity at length curve of North Pacific bluefin tuna (Chen et al. 2006) to approximate the batch fecundity at length of albacore tuna. In particular, the length of bluefin tuna at which batch fecundity was expected to be zero was  $L_0 = 160.7$  cm (Mangel et al. 2010). This parameter describing the maximum expected length at zero fecundity was a fraction  $c = L_0/L_{inf} = 0.5014$  of the asymptotic length of bluefin tuna, where  $L_{inf} = 320.5$  cm. We assumed that the asymptotic length at zero fecundity for albacore tuna had the same scaling constant  $c$  with  $L_{inf}$  as in bluefin tuna. As a result, we estimated  $L_0 = c \cdot L_{inf}$  under the three alternative growth curves for albacore (Table 1). Estimates of  $L_0$  were:  $L_0 = 73.4$  cm for Suda growth,  $L_0 = 60.2$  cm for Wells growth, and  $L_0 = 61.2$  cm for model-based growth.

There was also limited information on the average mass of developed albacore eggs, an input parameter that was needed for the steepness simulations. We approximated the average mass of albacore eggs by assuming that the expected egg diameter was approximately 1.0 mm as suggested by the size of advanced stage albacore eggs measured by Otsu and Uchida (1959, see Figure 12) off Hawaii and by calculating the spherical egg volume  $V = 4\pi r^3/3$  and associated water mass expected at a temperature of 25 °C (Table 1).

A total of 500 simulations were run for each 500 populations comprised of 500 individual fish to estimate the empirical distribution of stock-recruitment steepness values for a Beverton-Holt stock-recruitment curve for North Pacific albacore tuna under the alternative growth curves. Under the Wells growth curve, we found that the reported value of  $t_0 \approx -2$  did not match the expected egg and larval duration in the steepness calculation algorithm and as a result, we set the value of this parameter to be  $t_0 = -0.9$ , which was very similar to the values of  $t_0$  under Suda and model-based growth curves. We also

estimated parameters of a beta density  $f(h)$  that provided the maximum likelihood fit to the empirical steepness distribution from the population simulations, where the form of the fitted density was

$$f(h) = \frac{\Gamma(a_\beta + b_\beta)}{\Gamma(a_\beta)\Gamma(b_\beta)} h^{a_\beta-1}(1 - h)^{b_\beta-1}$$

with beta density parameters  $a_\beta$  and  $b_\beta$ . These fitted parameters can be used to set up a prior distribution for stock-recruitment steepness using the beta density (see Figures 1.1-1.3).

Results under the Suda growth curve indicated that the mean steepness was  $\mu_h=0.84$  with a standard deviation of  $\sigma=0.04$  (Figure 1.1). Similar results were obtained under the Wells growth curve which had a mean steepness of  $\mu_h=0.85$  with  $\sigma=0.03$  (Figure 1.2). The model-based growth curve had a higher mean steepness of  $\mu_h=0.95$  with  $\sigma=0.01$  (Figure 1.3). Thus, the results suggested that the North Pacific albacore tuna stock had a resilient to highly resilient stock-recruitment relationship depending upon the choice of growth curve. The results also conformed to the expectation that faster somatic growth, as indicated by higher values of the von Bertalanffy  $k$  parameter, was associated with higher resilience in the stock-recruitment relationship. Overall, the results indicated that the mean steepness of North Pacific albacore was less than unity (i.e.,  $\mu_h=1$ ). In this context, assuming that mean steepness is unity is a biologically implausible assumption because setting  $\mu_h=1$  implies that there is an infinite amount of compensation in the stock-recruitment relationship (Brodziak et al. 2002, Mangel et al. 2010).

A sensitivity analysis to the assumed value of age-0 natural mortality rate  $M(0)=0.30$  was also conducted. In this analysis, we doubled the value of age-0 natural mortality to be  $M(0)=0.60$  and reran the steepness simulation algorithms for each of the growth curves. As expected (Mangel et al. 2010, see equation 29), increasing the natural mortality rate schedule reduced the estimates of mean steepness under each of the growth curves (Figure 2). Results of the sensitivity analysis indicated that doubling the age-0 natural mortality rate would reduce the mean steepness estimates under the Suda, Wells, and model-based growth curves to  $\mu_h=0.79$  (-6%),  $\mu_h=0.81$  (-5%), and  $\mu_h=0.93$  (-2%), respectively.

Table 1. Continued.

|    |                |                  |   |
|----|----------------|------------------|---|
| 13 | sig50          | double           | The $\sigma_M$ parameter for logistic probability of maturity-at-age function. For albacore $\sigma_M = 0.05$   |
| 14 | nu             | double           | <u>Not applicable for albacore analysis.</u><br>The $\nu$ parameter in the gamma density for natural mortality rate for production model (eqn 31 in Mangel et al. (2010)).  |
| 15 | Mbar           | double           | <u>Not applicable for albacore analysis.</u><br>Expected value of natural mortality rate in gamma density for production model (eqn 31 in Mangel et al. (2010. Fish and Fisheries 11:89-104.)).   |
| 16 | h_inc          | double           | Mesh of the grid to evaluate steepness. This value of h_inc is linked to lmax above via $lmax=(0.8/h\_inc)+1$ , e.g., if h_inc=0.005, then lmax=161. For albacore h_inc = 0.01  |
| 17 | r_sex          | double           | The sex ratio or fraction (r) of males at birth where (1-r) is the fraction of females at birth. For albacore r = 0.5   |
| 18 | Spawn_season   | double           | The fraction of the year when spawning occurs, e.g., if the spawning season lasts 6 weeks, then Spawn_season is 6/52. For albacore, Spawn_season = 12/52.   |
| 19 | Spawn_interval | double           | The average number of days between individual spawning events during spawning season, e.g., if Spawn_interval is 3 days and spawning season last 3 weeks, then the expected number of spawning events would be 21/3=7 events. For albacore, Spawn_interval = 3.33 |
| 20 | B0_fl          | double           | The parameter $B0_{fl}$ in the fecundity (units are numbers of eggs) at length (units are cm) relationship<br>$F(L) = (B0_{fl} + B1_{fl} \cdot L) \cdot 10^5$<br>Suda growth: B0= -237.89<br>Wells growth: B0 = -194.91<br>Model-based growth: B0 = -198.15       |
| 21 | B1_fl          | double           | The parameter $B1_{fl}$ in the fecundity (units are numbers of eggs) at length (units are cm) relationship<br>$F(L) = (B0_{fl} + B1_{fl} \cdot L) \cdot 10^5$<br>For albacore, B1 = 3.2393  |
| 22 | sig_mcgurk_el  | double           | Standard deviation of log-log regression for daily natural mortality rate. Estimated to be 0.9177698 in Mangel et al. (2010).   |
| 23 | sig_mcgurk_j   | double           | Standard deviation of log-log regression for daily natural mortality rate. Estimated to be 0.963802 in Mangel et al. (2010).  |
| 24 | lhstructure    | integer          | Indicator for life history structure where lhstructure=1 is the production model and lhstructure=2 is the age-structured model. For albacore, lhstructure = 2   |
|    | W_el[1]        | double           | Initial wet egg mass (units are g). For albacore W = 0.000522   |
| 25 | M_el[1]        | double           | <u>Not applicable for albacore analysis.</u><br>Initial accumulated daily instantaneous mortality.  |
| 26 | Mbar_a         | double<br>[Amax] | Natural mortality rate at age vector for ages 0,1,..., Amax. For albacore, M(j) = 0.30 for all ages $j \leq Amax$   |
